The U.S. army Biogedical Research and Development Laboratory has conducted a study of the operation of the industrial liquid waste treatment facility at Holston Army Ammunition Plant (HSAAP) from startup in 1983 through August 1986. The HSAAP waste treatment plant includes anoxic dentirification filters, a trickling filter, activated aludge treatment, and dual media filtration, and currently receives about 5 mgd of process wastewaters containing moderate chemical oxygen demand and nitrate levels and low, but significant, levels of FDX, HMX and nitramine coproducts. Daily performance and operational parameters have been compiled and analyzed, and the overall efficiency of the treatment scheme has been evaluated. It is concluded that this treatment facility is adequate for HSAAP for the foreseable future, but does not represent the best choice for a new EDX facility elsewhere. 10. The U.S. army Biomedical Research and Development Laboratory has conducted a study of the operation of the industrial liquid waste treatment facility at Holston Army Ammunition Plant (HSAAP) from startup in 1983 through August 1986. The HSAAP waste treatment plant includes anoxic denitrification filters, a trickling filter, activated sludge treatment, and dual media filtration, and currently receives about 5 mgd of process wastewaters containing moderate chemical oxygen demand and nitrate levels and low, but significant, levels of HDX, HMX and nitramine coproducts. Daily performance and operational parameters have been compiled and analyzed, and the overall efficiency of the treatment scheme has been evaluated. It is concluded that this treatment facility is adequate for HSAAP for the foreseable future, but does not represent the bast choice for a new HDX facility elsewhere. PREFACE

This study has been performed under R&D Project No. 1L162720D048, US Army Toxic and Hazardous Materials Agency, and is part of the Army Material Command Pollution Abatement and Environmental Control Technology Program. Project Officer is Janet Mahannah. The authors gratefully acknowledge the assistance of Holston Army Ammunition Plant and Holston Defense Corporation personnel in preparing this report. We note in particular the contribution of Patricia Marsack Evans, who patiently answered endless questions on details of plant operations and who responded promptly and cheerfully to repeated requests for more data. Johnny Ray Evans and Mike Mills also gave generously of their time. Much of the field data was collected by Mark O. Schmidt, and all nitramine analyses were performed by Ernst E. Brueggemann, both of the US Army Biomedical Research and Development Laboratory (USABRDL).

Elizabeth T. Paulson was a student at West Virginia University under contract to USABRDL during the period of performance of this study. The services of Robert P. Carnahan, University of South Florida, were retained under the Intergovernmental Personnel Act of 1970.

INTRODUCTION

In early 1985, the U.S. Army Biomedical Research and Development Laboratory (USABRDL), at that time the U.S. Army Medical Bioengineering Research and Development Laboratory, undertook an evaluation of performance of the major unit processes of the Holston Army Ammunition Plant (HSAAP) wastewater treatment facility. It is understood that this evaluation will provide guidance for selection of appropriate technologies for treating wastewaters at a projected new RDX manufacturing plant (X-Facility); it is not intended as a critique of the present HSAAP treatment facility.

To the best of our knowledge, all relevant documented operational and performance data from June 1983, the date of initial startup, through August 1986 were collected. Additional parameters were measured as deemed necessary through grab samples, and periodic readings were taken from various gauges in the treatment plant control room. Facility specifications were obtained from the design calculations of Clark, Dietz and Associates, and operational practices were learned through frequent discussions with personnel at Holston Defense Corporation (HDC), the operating contractor. At least one individual from BRDL was on site at HSAAP continuously from June 1985 through August 1986. After preliminary examination of the data, it became apparent that stabilized operation of the wastewater treatment plant was achieved near the end of 1984; we therefore have chosen to evaluate in detail the 20 months of operation from January 1985 through August 1986.

In evaluation of the HSAAP wastewater treatment facility, two important aspects of the ammunition plant must be understood. First, HSAAP is not a continuous production facility as such; RDX is made in a continuous process, but HMX is made in a batch process. There are as many as 60 different products, and while nearly all incorporate RDX or HMX, the manufacturing processes and hence the wastes generated (spent solvents, e.g.) can be quite variable. In this respect, HSAAP resembles a fine chemicals manufacturer. Second, the present wastewater treatment plant was designed to treat a wastewater that it has not encountered. All process design research presumed a level of water conservation yet to be practiced in production. Thus, the present wastewater treatment plant, constructed to accommodate 50 percent of the projected full mobilization wastewater average discharge of 12.7 mgd (15 mgd maximum), already is handling an average of 5 mgd with production at approximately 15 percent of full mobilization capacity. The combined wastewater is therefore substantially weaker with respect to most parameters than was envisioned when the plant was designed. (It is not anticipated that an increase in production will result in a proportionate increase in wastewater discharge; a substantial fraction of the present flow, such as infiltration, is independent of the level of production. 2) In evaluating individual unit processes, we have documented and evaluated performance in terms of the actual applied wastes, but we have also speculated on the performance that might be expected with the more concentrated wastes.

DESCRIPTION OF FACILITIES

The combined wastewater treatment plant receives three separate wastestreams. The largest of these, approximately 4 mgd, contains the production wastes from Area B, as well as some storm run-off from both active and inactive production facilities. Area A wastewaters, approximately 0.5 mgd, are transported 5 miles from Kingsport, TN, by pipeline. An additional 0.5 mgd is settled filter backwash from the river water treatment plant. This latter stream, like storm run-off, is significant in that it imposes a hydraulic burden on the biological treatment plant, but very little waste burden. The manufacturing operations are described by Hash, Evans and Simerly as follows:

Area A

- 1. Azeotropic distillation to concentrate dilute acetic acid to 99+ percent purity. Acetic acid is used in explosives manufacture and in the production of acetic anhydride.
- 2. Thermal dehydration of concentrated acetic acid to produce ketene as an initial step in acetic anhydride manufacture.
- 3. Absorption of the ketene to produce crude acetic anhydride and the subsequent recovery of unreacted acetic acid.
- 4. Refinement of crude acetic anhydride by distillation.
- 6. Manufacture of producer gas for use as fuel in acetic anhydride production.

Area B

- 1. Nitrolysis of hexamethylenetetramine (dissolved in acetic acid) using nitric acid/ammonium nitrate, and acetic acid to produce crude RDX and HMX.
- 2. The recovery of crude RDX from unreacted materials.
- 3. The recrystallization of RDX and HMX.
- 4. The production of a variety of explosive compositions, the most notable of which is Composition B, a mixture of RDX, TNT, and wax.
- 5. The packaging of explosives for shipment.
- 6. The manufacture and concentration of nitric acid.
- 7. The recovery of spent acetic acid for refinement at Area A.
- 8. The recovery of ammonia from the destruction of explosive-contaminated sludges.

As indicated above, the combined wastewater treatment facility was designed for an average flow of 12.7 mgd at 100 percent mobilization (11.5 mgd from Area B), and constructed for half this flow, with a few exceptions.

Daily flows, averaged monthly, to and from the treatment facility are shown in Figure 1 and Table 1 for the period under study. (The settled filter backwash from the river water treatment plant, mentioned above, makes up most of the postthickener overflow.) It will be noted that the plant discharge exceeds the combined individual wastestreams by approximately 8%; it is not known whether this difference results from unidentified water sources, such as infiltration and inflow, or simply represents cumulative errors in flow totalizers. Individual treatment units, diagrammed in Figure 2, are as follows:

- 1. Preliminary (Explosives) Settling Basins
- 2. Neutralization Basins
- 3. Anoxic Filters
- 4. Aerobic (Trickling) Filter
- 5. Aeration Basins
- 6. Secondary Clarifiers
- 7. Multimedia Filters
- 8. Prethickener
- 9. Aerobic Digesters
- 10. Postthickeners
- 11. Filter Presses

For the most part, routine operational details for these units are adequately discussed in U.S. Army Environmental Hygiene Agency Water Quality Engineering Study No. $32-24-6871-85^4$ and will not be repeated here.

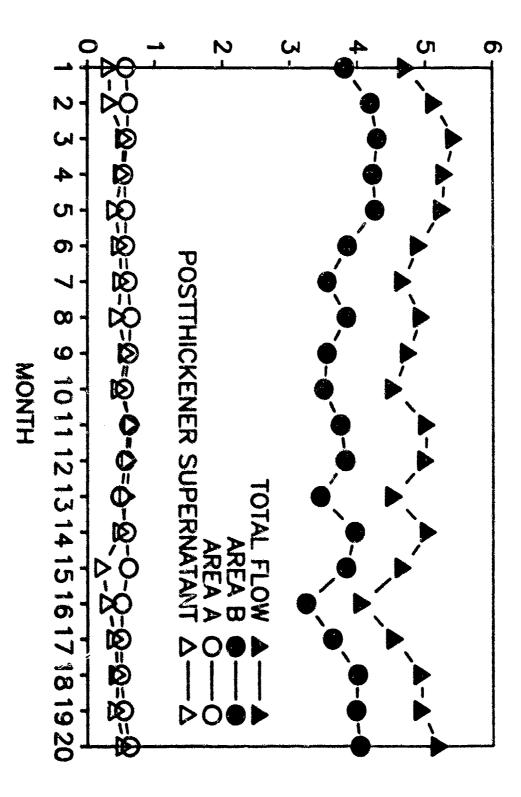

Figure 1. Monthly Average Wastewater Discharge, 1 Jan 85 - 31 Aug 86.

a. Concentration in mg/L calculated for current average 5 mgd discharge.

SAMPLING AND ANALYSIS

All data for wastewater contaminant concentrations and SVIs reported by Holston Defense Corporation are based on grab samples collected at each shift (three times per day) except for BOD values, which are taken from composite samples. Analyses were conducted according to Standard Methods. (BRDL personnel shared the laboratory at the wastewater treatment plant with the analysts, and can attest to the care with which this work was performed.) Flow data are taken from totalizers. Grab samples for nitramine analysis were collected by BRDL personnel and kept refrigerated until flown to Fort Detrick for HPLC analysis according to the method of Brueggemann.

It should be noted that discharge from the postthickeners to the neutralization basin is not continuous; periodic surges from this source (and perhaps others) account for some of the wide variability observed for parameters measured at the neutralization basin and elsewhere.

UNIT PROCESS EVALUATION

Preliminary (Explosives) Settling Basins

Preliminary settling basins consist of two parallel rectangular tanks, 190 ft long, 25 ft wide and 10 ft deep, with sludge collectors. These tanks are intended to remove settleable materials, in particular explosive chemicals, from Area B wastewaters. In practice, precipitation of solids has been much less than the projected 2000 lb/day for full mobilization, and the explosive chemical content is too low to allow open burning of the sludge. In order to avoid processing the sludge, which would probably be restricted to a Class A landfill, HSAAP allows the raw wastewaters to pass through the basins without sedimentation, thereby adding a small burden of solids (no more than 20 mg/L) to the biological treatment system. From June 1985 through August 1986 the munitions chemicals in Area B wastewaters, with the possible exception of HMX, were never observed to approach their solubility limits. Thus, the proliminary settling basins are irrelevant to operation of the HSAAP wastewater treatment plant, and would probably not be needed for X-Facility provided that there are strategically placed traps in production buildings to collect wastewater-borne solid explosives, as there are at HSAAP. The equalization capacity of the basins under current hydraulic loading is only 3.4 hours, so they don't perform a useful function in that regard, either. However, the basins have proved invaluable as surge basins to hold unscheduled dumps or spills at HSAAP; similar spill capacity may be needed for X-Facility.

Neutralization Basins

Neutralization basins were constructed to provide 100 percent, rather than 50 percent, of full mobilization capacity. They consist of two basins with two cells each measuring 13.6 ft by 13.6 ft by 10 ft and high-capacity mixers. Wastewaters are routed through the top basin to the anoxic filters (see below), and overflow from the anoxic filters is routed through the bottom basin. Under the current regime, the hydraulic retention time is 3.9 to 4.4 min/cell, depending on which wastestreams are treated, rather than the design value of 1.4 min/cell. Besides neutralization, the basins provide for addition of nutrients (phosphoric acid, ammonia, and acetic acid) as needed. During the period observed by USABRDL, no chemicals were added; the alkaline postthickener supernatant kept the overall pH at a satisfactory level, and nutrient addition was not considered to be necessary. (We believe, however, that current phosphorus levels are suboptimal for biological treatment of wastewaters, as is discussed later in this report.) Thus, the neutralization basins serve solely as mixing basins for the various waste streams, and it has not been possible to evaluate their intended performance. However, assuming that X-Facility utilizes biological wastewater treatment, the ability to add nutrients and control pH will be required. Nitrate loading to the denitrifiers -- regardless of the type chosen -- will probably be lower for X-Facility, and BOD loading will be higher, so that addition of acetic acid or other carbon supplement should not be necessary. Monthly average chemical oxygen demand (COD) levels at the neutralization basin and other stations within the wastewater treatment plant are presented in Table 3 and Figure 3.

a. Calculated for period when not identical with anoxic effluent.

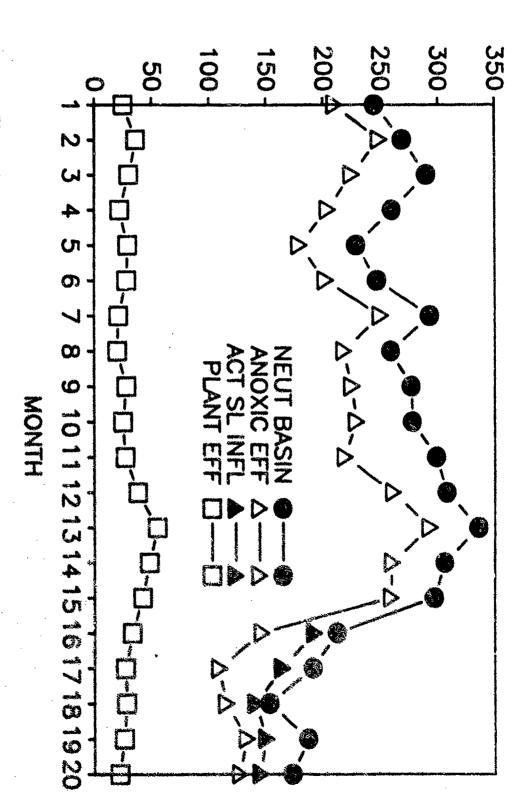

Figure 3. Monthly Average Wastewater COD, 1 Jan 85 - 31 Aug 86.

Anoxic Filters

Design

The anoxic filters consist of four upflow cells each 28 ft by 36 ft in area with a media depth of 10 ft and a liquid depth of 22 ft including the distribution system. Each cell contains corrugated sheet plastic media with a specific surface area of 68 ft 2 /ft 3 , close to the minimum recommended by EPA. The design hydraulic loading is 1.2 gpm/ft 2 ; the design waste loading is 3.7x10 $^{-4}$ (winter) to 4.1x10 $^{-4}$ (summer) lb/day NO₃-N removed per ft 2 of packing surface, compared with a maximum of 1.3x10 $^{-4}$ lb/day-ft 2 recommended by the Environmental Protection Agency (EPA).

Operation

Nitrate loadings are highly variable, as illustrated by daily averages (Appendix C) and monthly averages (Table 4 and Figure 4), owing to the decision of HSAAP to discharge two concentrated nitrate ponds, dating back to the origin of the ammunition plant, through the wastewater treatment system. From startup in 1984 until mid-April, 1986, Area A wastewater was mixed with Area B wastewater and postthickener supernatant in order to take advantage of the strong, degradable Area A wastes in denitrification. Thereafter, through August 1986, Area A wastewater has bypassed the anoxic filters and gone directly to the aeration basins. The hydraulic loading rate has averaged 0.75 to 0.85 gpm/ft² cell surface, depending on whether or not the influent included Area A wastewater, with four cells in service. With three cells in service, which has been the more common practice for reasons given below, the average has been 1.0 to 1.1 gpm/ft². Nitrate concentrations commonly fell in the range of 20 to 40 mg/L for Area B wastewater and 10 to 20 mg/L for the anoxic effluent (Table 4). The average waste loading for the 20-month study period (Table 5) was 1.4x10⁻⁴ lb per day per ft² of packing surface with four basins in service, or 1.9x10⁻⁴ lb/ft²-day for three basins.

As the attached biological growth sloughs from the media, heavy particles settle to the bottom of the distribution system to form a sludge layer, while the lighter particles are carried over the weir with the effluent. The sludge is pumped out on a regular schedule. (The design calls for application of the anoxic sludge to the top of the trickling filter, but this is no longer practiced.) Periodically, the attached growth is flushed from the media by concentrating the total flow to a single cell.

Performance

Table 4 presents monthly average nitrate nitrogen levels at various stations within the treatment plant. Nitrate removals have, for the most part, been acceptable but below expectations; there have been occasional excursions above permit limits. The average reduction in nitrate concentration between the Area B wastewater and the plant effluent is 70%, but about 20% results from dilution, and 10% is due to reduction through other processes; the average reduction of nitrate applied to the anoxic filters is slightly less than 50%. The average nitrate nitrogen level in the influent to the anoxic filters during the study period, 21 mg/L, is nearly identical to the design value, but whether because of deceased organic loading or some other reason, this system fails to achieve its design performance of 95%

a. Operational parameters were changed during this month.

nitrate removal. Denitrification is strongly pH-dependent. The optimum is approximately pH 7; however, pH values in the acid range permit denitrification in the presence of dissolved oxygen (DO), while anaerobic conditions are essential for denitrification in alkaline solution. In spite of the absence of pH control, the neutralization basin pH varies between 6 and 8 with little diurnal variation, except for brief occasions when discharge of alkaline postthickener supernatant drives the pH to 9 or higher. Lacking ambient DO values for the anoxic filters, we can only guess that pH is not the cause of their poor performance. Although there is no firm correlation between anoxic influent and plant effluent nitrate values, prolonged application of nitrate above 30 mg/L appears to result in permit violations. There is little excess capacity in this part of the system, and a substantial increase in production will necessitate cutting off discharge from the historic nitrate ponds.

The relation between nitrate nitrogen removal and COD removal is given by:

COD removed = $3.71 \times NO_3 - N$ removed $\div 2.3 \times NO_2 - N$ removed $\div 1.3 \times DO$

where DO is the dissolved oxygen content of the influent. The DO level in the neutralization basin averaged 3.5 mg/L from January through August, 1986. The only nitrite data we have suggest that nitrite levels in the neutralization basin may be roughly 10% of the total. From the data in Tables 3 and 4 it is calculated that the average COD removal over the 20 month observation period exceeded that required for removal of nitrate and DO alone (neglecting any nitrite contribution) by 20%; some of the excess may be due to nitrite removal.

The principal problem in operation of the anoxic filters has resulted from excessive biological growth, uncontrolled by frequent flushing. Over a period of a month or more, depending on the season and nitrate loading (warm weather and high loadings are worst), the growth begins to restrict the wastewater flow; eventually, the media becomes completely plugged, and the blocks of media are displaced and bypassed by the wastewater. The cell must then be taken out of service and the media blocks cleaned with a fire hose, a labor intensive undertaking that eventually destroys the media. During our period of observation, at least one cell was out of service most of the time. The media in one cell was replaced with media from the trickling filter, which has half the specific area and hence bigger passages. (We have not attempted to correct for the corresponding reduced packing surface in Table 5.) This

Some data concerning performance of the anoxic filters are conflicting. Composited samples collected during 23 to 30 June 1986 indicated an average nitrate nitrogen removal of 81% in the anoxic filters. It Grab-samples collected each shift for the same period indicated a removal of 64%. Whether the difference represents a difference in sample treatment or a statistical anomaly is unknown to us.

delayed but did not eliminate the problem, and initial nitrate removal was poorer. Whether this problem results from the high nitrate loading, the low flow rate (resulting in low shear forces), a unique biological growth, or some combination thereof is unknown, and as of August, 1986, no satisfactory solution was in hand. HDC personnel believe that part of the problem can be attributed to a poor wastewater distribution pattern during the flushing cycle. Among recommendations for correcting this problem are increasing the flow rate (hence the shear forces) through effluent recycle, selecting a media with more direct, vertical passages, implementing an air scour system, and placing a screen upstream to intercept occasional large chunks of materials from the manufacturing facility. The practice of using spacers to provide vertical separation of approximately 6 inches between media blocks is also worth consideration.

Until the problems in operation of the anoxic filters at HSAAP are resolved, the Army would be poorly advised to duplicate this system for X-Facility. Alternative attached growth systems, such as a totally submerged rotating biological contactor, and suspended growth systems could profitably be evaluated. It should be noted that Carnahan et al. have found that the much stronger wastes anticipated by the U.S. Army Armament Research and Development Command for X-Facility cannot be denitrified using upflow anoxic columns. 12

Aerobic (Trickling) Filt

Original studies by Grady and Etzel indicated that Area B wastewaters could not be treated by activated sludge because of severe sludge bulking. 13 Later studies by Hash, et al. confirmed the problem with bulking, but indicated that aerobic filters, recommended by Grady and Etzel, could not achieve the effluent quality required. 3 Aerobic filters followed by activated sludge were much less susceptible to sludge bulking and provided an acceptable effluent. Both studies used composited production wastewaters amended with appropriate organic compounds (acetic acid, cyclohexanone, acetone, n-butanol, and hexamethylenetetramine) to raise the COD to a level projected for HSAAP combined wastewater following water conservation modifications.

The present aerobic filter system consists of a single natural draft tower 65 ft in diameter with a media depth of 24 ft. The media is corrugated plastic with a specific area of 30 ft²/ft³. The design hydraulic application rate is 1.5 gpm/ft² filter syrface, with provision for recycle when the actual flow drops below 0.75 gpm/ft². This system was in operation from June 1983 through August 1984, during which time the hydraulic application rate was approximately 1.0 gpm/ft². The COD application rate cannot be defined for most of this period, but can be estimated to be 110 lb/1000 ft³/day (assuming an anoxic filter effluent COD of 200 mg/L and 400 lb of anoxic sludge wasted per day). These numbers are all near the lower end of the range suggested by EPA for roughing filters. Aerobic filter effluent values varied widely but commonly fell in the range of 40 to 140 mg/L during the last year of operation (Appendix F). Conservatively, this system achieves 50 percent COD removal, which is appropriate for a roughing filter.

The aerobic filter was removed from service when it became apparent that sludge bulking would not be a problem in the activated sludge treatment system. This decision is estimated by Holston Defense Corporation (HDC) to

have saved \$50,000 a year in pumping costs. Two circumstances may have made the aerobic filter unnecessary: first, the combined wastewater is little more than half as strong as projected, and second, the anoxic filters, under the high nitrate loading, may be serving as roughing filters. (Biological denitrification, by whatever technology, consumes approximately 4 lb of BOD per lb NO₃-N removed). Either of these circumstances could change, and it may become necessary to return the aerobic filter to service in the future. Should it be decided to utilize activated sludge for wastewater treatment at X-Facility, the experience at HSAAP does not provide much guidance concerning the need for a roughing filter. There is no substitute for a pilot study.

Activated Sludge

Design

Based on the studies of Hash, et al., the aeration basina are designed for a mean_cell residence time (sludge age) of 8 days and an aeration time of 6 hours. They consist of five completely mixed basins (Figure 5) of which four, with a total volume of 1.5 million gallons, were in service during the study period. (During much of 1986 the No. 2 basin was observed to be filled but not under aeration.) Although this complex system has some plug-flow characteristics, we have chosen to treat it as a single completely mixed basin for the purpose of computing performance parameters. Five floating aerators of 60 and 75 hp, providing 200 to 250 hp per million gal, maintained the dissolved oxygen at a more than adequate level of 4 to 6.5 mg/L during the summer months of 1986 in basin No. 3, which receives the heaviest COD loading. Two circular center feed clarifiers, 90 ft in diameter, are fed from a central splitter box. These clarifiers provide a design overflow rate of 565 gpd/ft², or a very conservative 400 gpd/ft² at 5 mgd. (The actual clarifie. loading will be roughly 10 percent higher because of recycle of clarified water, such as filter backwash and prethickener freshener.) Sludge collected at the bottom of the clarifiers is returned to the aeration basins by means of screw pumps. Sludge age is controlled by wasting mixed liquors from the splitter box.

Operation

Monthly average operational parameters for the activated sludge system are presented in Table 6. There appear to be no consistent trends other than a significant drop-off in applied COD and volatile solids during the last five months of the observation period. The most important single parameter for operation of an activated sludge system is probably the food-to-microorganism ratio (F/M), in this case calculated as the COD utilized per day divided by the total mass of mixed liquor volatile suspended solids (MLVSS) under aeration, i.e.:

$F/M = (COD_{infl} - COD_{effl})/X_vt$

where X_{Vt} is the concentration of volatile suspended solids (beams) and t is the detention time. Despite the variability in substrate loading and beams, HSAAP has succeeded in maintaining F/M in a relatively narrow range encompassing 0.45 day⁻¹ (Table 6 and Figure 6). This represents the high end for generally accepted F/M levels¹⁴, but it is probably appropriate for such a highly degradable substrate. The average influent of 5 mgd and the present

a. All calculations assume 1.5 million gal. under aeration.

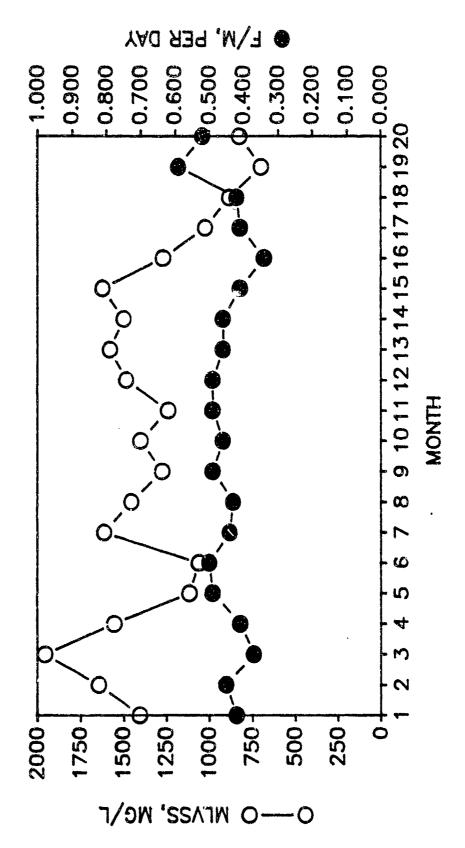

Figure 6. Monthly Average MLVSS and F/M, 1 Jan 85 - 31 Aug 86.

wasting rate of 125 gpm from the basins gives an aeration time of 7.2 hr and a sludge age of 8.4 days; the average values for the 20 months of the observation period have been 7.4 hr and 7.7 days, respectively. These values are within reasonable design limits. Mixed liquor suspended solids have generally fallen in the range of 1500 to 2500 mg/L, of which 65 to 75 percent (occasionally higher) is volatile.

Performance

At an effluent flow of 5 mgd, BOD5 discharge limitations are 19 and 38 mg/L daily average and daily maximum for May 1 through October 31 and 29 and 58 mg/L daily average and daily maximum for November 1 through April 30 (Table 2). (It is anticipated that discharge limits will be revised when production exceeds 50 percent of capacity.') As shown in Table 7, HSAAP has had no problem achieving these limitations; effluent BOD levels (after filtration) are commonly less than 4 mg/L. Influent COD's from the anoxic filters have been variable, falling in the range 250±100 mg/L (Appendix E); COD removals have consistently exceeded 80 percent. Monthly average COD levels at various stations are shown in Table 3 and Figure 3.

The organic removal rate coefficient, k_{BOD} , is calculated from the equation: 15

 $[S_o(S_o - S_e)]/X_vt = k_{BOD}S_e$

where

S_o = influent total BOD₅ S_e = effluent soluble BOD₅

Lacking influent BOD data for the aeration basins, we have assumed that $S_{\rm O}$ = $(COD_{infl} - COD_{effl}) + S_e$; this may slightly underestimate S_o , but should be sufficiently accurate for our purpose. Effluent BOD values are unusually low, indicating nearly complete utilization of biodegradable substrate, and as a consequence kgop values are high (Table 7). These results are not unexpected if, as has been suggested, 16 principal organic waste constituents from RDX production wastewaters are formaldehyde and formic acid, with lesser amounts of cyclohexanone, acetone, and acetic acid, inter alia. All these compounds are highly biodegradable, and in the case of formaldehyde one cannot eliminate the possibility of substantial chemical degradation through air oxidation. Of the nonbiodegradable portion of the influent COD, 5 to 8 mg/L can be attributed to nitramines, while much of the rest may be due to hexamethylenetetramine (hexamine). Temperature effects on kBOD are predictable, with late summer rates being nearly double late winter rates, corresponding to a difference of approximately 10°C (Appendix J). The anomalous low kgop for June 1986 is unexplained, but it accompanied the lowest observed influent COD, perhaps during a clean-up period.

Performance with respect to nutrients may be atypical for a chemical plant, since nutrients are not supplemented at HSAAP. Nitrogen and phosphorus requirements for activated sludge are generally taken to be 12.3% and 2.6%, respectively, of the weight of biomass wasted. For an average wastage of 4300 lb/day of biomass (Tables 7 and 8), a 5 mgd wastestream would require nitrogen and phosphorus levels of 12.7 mg/L and 2.7 mg/L respectively. Not all of this needs to be added; some nutrient values are recovered during digestion of the waste sludge (see below) and returned to the head of the

plant. A rule of thumb states that for every 100 parts of BOD applied the influent wastewater should contain 5 parts of nitrogen and one part of phosphorus; this would correspond to 9 mg/L and 2 mg/L, respectively, for the stream entering the aeration basins, which has an estimated average BOD level of 187 mg/L for the 20 month period of observation (Table 7). Nitrogen is usually added in the reduced form (ammonia, e.g.), but wastewater at the head of the plant contains very little ammonia nitrogen (commonly less than 1 mg/L), and successful operation of the activated sludge system depends on utilization of nitrate nitrogen. averaging 11 mg/L (Table 4), discharged from the anoxic filters. Some very limited data suggest that the total phosphorus level at the head of the plant is usually less than 1 mg/L. Most of the phosphorus is in the form of boiler water treatment chemicals from Area A, and is biologically unavailable. A biological wastewater treatment pilot plant (sequencing batch reactor) was operated at HSAAP during the first 8 months of 1986 in parallel with the main plant; great difficulty was encountered in generating an adequate biomass level until a phosphorus supplement was added. 17 While one must acknowledge the success of the activated sludge system in destroying degradable substrate, it is our belief that the HSAAP treatment plant is phosphorus-limited, and that this will become an increasing problem with increasing wastewater strength.

Total suspended solids limitations are 12 and 24 mg/L daily average and daily maximum at 5 mgd (Table 2). With few exceptions, the clarifier effluent solids have averaged <20 mg/L with mixed liquor suspended solids levels of 1500 to 2500 mg/L, so for the most part the dual media filters, discussed below, have not been overloaded. (A temporary increase in clarifier effluent solids can be controlled by polymer addition at the splitter box; this strategy was successfully employed when one of the clarifiers was taken out of service for maintenance and the hydraulic load to the second was doubled.) The sludge volume index (SVI), a measure of solids settleability, is compared with the mixed liquor suspended solids (MLSS) levels for the observation period in Table 8 and Figure 7. SVI values are generally low, indicating good settleability, and they roughly parallel MLSS values.

We conclude that this lightly loaded activated sludge system is performing satisfactorily, even without phosphorus supplement. There have been some problems; sludge returned from the clarifiers at a ratio of 1.7:1 has been only twice as concentrated as the mixed liquors (based on limited BRDL sampling), and never more than 5000 mg/L, about half the usual value for return sludge. During spring and summer of 1986, the volatile solids under aeration fell below 1000 mg/L, even though the COD loading was increased in mid-April by rerouting the concentrated, highly degradable Area A wastewaters directly to the aeration basins. The system appeared at risk of upset; however, in August 1986 the solids level began to recover, perhaps coincident with reduction in the sludge return ratio to 1.0:1) It seems likely that a much higher waste loading and a somewhat higher hydraulic loading could be accommodated by the present system. Whether and at what loading the sludge bulking problem that plagued the pilot studies will reappear is unknown.

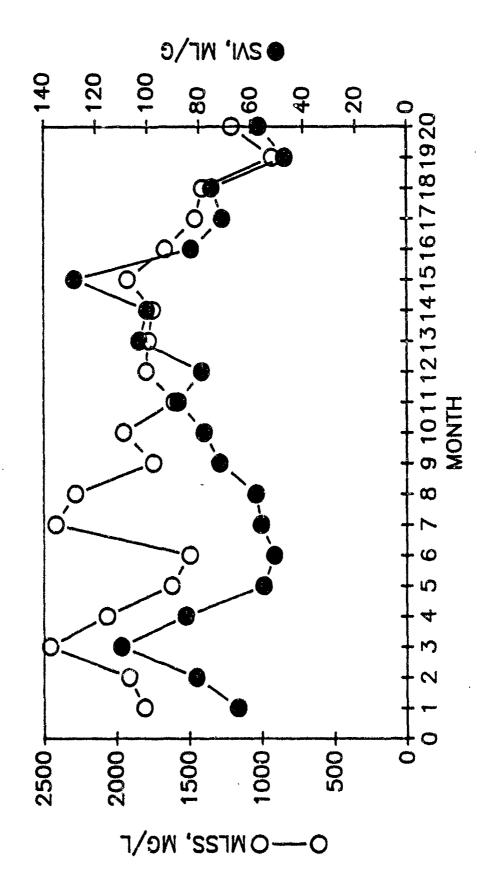

Figure 7. Monthly Average MLSS and SVI, 1 Jan 85 - 31 Aug 86.

Dual Media Filters

Design

The final filtration system consists of four dual media filters (anthracite and sand), each 16 ft 4 in square, a clearwell basin and a backwash tank. The design hydraulic loading is 4 gpm/ft², the design solids capture is 0.69 lb/ft² per run, and the length of each filter run is approximately 23 hours for the design suspended solids removal of 15 mg/L and 10 ft terminal head loss. The backwash water requirement (taken from final effluent in the clearwell) is 65,200 gal/filter/backwash, or 272,000 gal/day for the conditions stated. The backwash water is eventually returned to the aeration basin, so imposes an additional load on the clarifiers. A subsurface agitator, which aids in cleaning the expanded bed during backwash, draws at a rate of about 400 gal/min (during operation) from the river water supply; this increases the effluent discharge relative to the plant influent.

Performance

Filtration for removal of biological solids is troublesome in comparison with removal of suspended silt, e.g., and this system is no exception. However, with the effluent limitations imposed (Table 2), there are no reasonable alternatives, and, everything considered, the system has functioned satisfactorily. Solids removal data for the dual media filters are summarized in Table 9. There is no strong relation between solids removal and backwash volume (Figure 8), but it may be noted that the average solids removal of 590 1b per day for the 20 month observation period, and the average total backwash volume of 86,000 gal/day correspond to a solids capture of 1.7 lb/ft² per run. or nearly 2.5 times the design value. This indicates that the dual media filters are hydraulically limited, and that substantially higher solids loadings could probably be accommodated without degrading performance. the current production schedule, the effluent limitations allow discharge of about one third of the total effluent without filtration, at the option of the plant operator. This may account for the large shift-to-shift and month-tomonth variations observed in the suspended solids level of the plant effluent.)

Prethickener

The prethickener, 34 ft in diameter, is designed for a solids loading rate of 4.7 lb/day/tt², a surface overflow rate of 300 gpd/ft², and an underflow solids concentration of 2.5 percent. A typical mixed liquor suspended solids concentration of 1500 mg/L, at a wasting rate of 125 gpm, gives a solids loading rate of 2.5 lb/day/ft² and a surface overflow rate of about 200 gpd/ft². To prevent anaerobic conditions from developing in the prethickener, freshener water is drawn from the clarifier effluent to increase the overflow rate. The prethickener overflow is returned to the aeration basins. The underflow concentration is not measured, but data from the aerobic digesters, described below, suggest an underflow solids level of about 1.7 percent. The prethickener is underloaded; however, there is no reason to believe at this time that it cannot meet its design specifications.

a. Calculation based on "Plant discharge" column, Table 1.

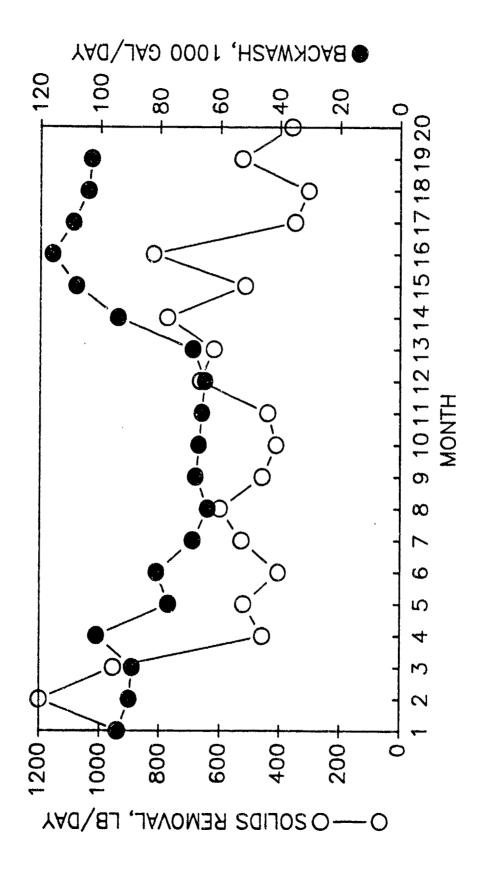

Figure 8. Monthly Average Final Filter Data, 1 Jan 85 - 31 Aug 86.

Aerobic Digesters

Two aerobic digesters, 28 ft by 84 ft in area and 12 ft deep (plus freeboard), have a design combined flow of 20,500 gpd, solids loading of 4,276 lb/day, and a detention time of 20 days. Design calculations assume an oxygen requirement of 2 lb/lb of solids destroyed, an oxygen transfer rate of 2 1b/hp-hr, and 55 percent volatile solids destruction. Limited summer sampling by USABRDL indicates a digester sludge solids concentration of about 11.000 mg/L and a volatile solids concentration of 6000 mg/L, corresponding to 50 percent digestion of volatile solids, assuming that the activated sludge had a volatile solids ratio of 70 percent. The influent to the digesters (i.e., the prethickener underflow) would have had a total solids level of about 1.7 percent, corresponding in turn to a flow of 16,000 gpd and a detention time of 25 days. The aerobic digester, though well underloaded at 2250 lb of solids per day, does not appear to destroy volatile solids as effectively as would be expected. The reasons for this are obscure, since the design is conservative. This has not been a problem, however, since the sludge is readily dewatered in subsequent steps.

Postthickeners

The 100 percent mobilization design calls for four postthickeners: three for alum sludge from the river water filter plant and one for biological sludge from the aerobic digesters. Three have been constructed, each 45 ft in diameter with a liquid depth of 10 ft. The design solids loading rate is 2.67 lb/ft², and the surface overflow rate is 300 gal/day/ft². A freshener stream from the clarifier effluent is available to maintain aerobic conditions in all three postthickeners, but it appears not to have been utilized most of the time. Through May, 1986, the alum and biological sludges were combined. This had the advantage of utilizing excess chemicals from the alum sludge to improve settling in the combined sludge; however, it greatly increased the cost of sludge disposal, since the biological sludge is considered to be a hazardous waste, and the addition of alum sludge more than doubled the total weight. During June, 1986, operations were changed to permit separate dewatering of the sludges. (Delisting of the biological sludge was achieved in December 1986.)

Since most of the solids applied to the postthickeners have been filter plant solids, we cannot quantitatively evaluate the system in terms of its treatment of biological solids. However, dewatering has not been a problem after separation of the sludges, so the system appears to be functioning satisfactorily.

Filter Presses

We do not have design data for the two filter presses. They are basically plate and frame assemblies with cloth filters. Operation has been relatively trouble-free, and a very satisfactory filter cake solids content of 33-35 percent is consistently achieved. The only problem has been that dewatered sludge tends to accumulate around the sludge inlet at the center of each filter plate. If not removed, this accumulation can break the plate in the next cycle. Removal of this accumulation is easily accomplished with a spatula; this adds perhaps 5 to 10 minutes to each cycle.

Filter presses are expensive relative to other sludge filtration systems; capital costs are high, and operational costs for chemicals, namely lime and ferric chloride, are not inconsiderable. However, performance of the units at HSAAP has been generally excellent. Considering that sludge management is commonly the most troublesome aspect of wastewater treatment plant operation, filter presses seem well worth the price for this application.

MUNITIONS DEGRADATION

During the last six months of 1985, nitramine concentrations in the neutralization basin averaged 4.6 mg/L for RDX, 1.8 mg/L for HMX, 2.4 mg/L for TAX, and 1.3 mg/L for SEX; plant effluent concentrations indicated overall removals of 43, 13, 100, and 0 percent, respectively (Table 10 and Appendix L). There is a reduction of about 25 percent in nitramine levels between the Area B influent and the neutralization basin; this is accounted for by dilution from Area A influent and the water treatment plant discharge. Nitramine data for the entire 20 month observation period are limited, but as shown in Figures 9 and 10, there is relatively little variation in influent and effluent concentrations.

For RDX, HMX, and SEX degradation took place exclusively in the anoxic filters; TAX was degraded as well in the aeration basins. However, it should be noted that, for all nitramines except TAX, the final effluent level is actually higher than from the anoxic filters. There are two possible explanations for this: (1) the nitramines are partially reduced in the anoxic filters, then reoxidized in the aeration basins and (2) the nitramines are taken up by the anoxic biomass and released when the biomass is consumed in the aeration basins. Although the first explanation is consistent with the observation by McCormick et al. that nitramines are progressively reduced through stable intermediates by anaerobic treatment 18, the second explanation is in agreement with our observation that RDX, HMX, and SEX are sharply reduced in the first stage of an aerobic biodisc, then increase in subsequent stages. 19 We have not observed any substantial signals during the HPLC analysis of nitramines that would correspond to the nitrosamines reported by McCormick et al. TNT was not detected in any HSAAP wastewater samples at the detection limit of 0.05 mg/L.

SUMMARY AND RECOMMENDATIONS

- 1. The HSAAP wastewater treatment plant is a well-constructed facility of conventional design, built to accommodate half the average wastewater flow of 12.7 mgd and maximum flow of 15 mgd projected for full mobilization. Performances of specific units during the period 1 January 1985 to 31 August 1986 are summarized below:
- a. The upflow, fixed-film anoxic filters are the least satisfactory part of the system. Designed to provide 95% nitrate removal, they have achieved no more than 50% removal during the observation period. Furthermore, the filters are subject to frequent biomass plugging. The second problem should be correctable through fairly simple design modifications. The first problem may not be correctable, but should be acceptable at HSAAP provided that (1) discharge criteria are not lowered and (2) historic nitrate ponds at HSAAP are discharged to the wastewater treatment plant at a rate slow enough to prevent permit violations.
- b. The aerobic (trickling) filter was not operated during the observation period, but limited data are available for 1984. Organic removals of 50% or better were achieved.
- c. The activated sludge system has consistently achieved nearly complete removal of biodegradable organics using less than the available aeration capacity. Clarifiers are generally satisfactory. This system is lightly loaded in terms of organics and suspended solids.
- d. The dual media filters have substantially exceeded their design rate of solids capture. They are approaching their hydraulic limits, but are well underloaded in terms of applied solids.
- e. Sludge handling facilities (prethickener, aerobic digesters, postthickeners and filter presses) have performed satisfactorily, although the digesters appear not to destroy volatile solids as well as expected.
- 2. A munitions production rate equal to 15% of full mobilization has been accompanied by an average wastewater flow of 5 mgd or nearly 80% of present treatment plant capacity. The wastewater is much weaker than projected in the original design. The production rate could probably be doubled without expanding the treatment plant, provided that the total discharge not exceed 6 mgd.
- 3. Experience at HSAAP provides limited guidance for construction of a treatment plant at X-Facility, where the vastewater is expected to be several times stronger with respect to soluble parameters. It is recommended that the HSAAP anoxic filters not be duplicated for nitrate removal. The combination of aerobic filter and aeration basins will probably reduce organics in the stronger wastewater to an acceptable level, but it is recommended that a combined aerobic/anoxic alternative, such as a sequencing batch reactor or a continuous oxidation ditch, be given serious consideration.

EPILOGUE

In the latter part of 1986, after USABRDL had completed its studies, the decision was made to bring the aerobic filter back on line, while reducing the number of aeration basins in service. This would result in a net energy saving while still meeting the discharge limits for BOD_5 (Table 2). As of November 1987, only Basin 5 (Figure 5), with a capacity of 0.6 million gallons, was in service. Historic nitrate ponds are no longer discharged to the waste treatment facility; influent and effluent NO_3 -N levels are currently about 5 mg/L and 2 mg/L, respectively.

APPENDIX M

GLOSSARY OF TERMS

BOD	Biochemical oxygen demand
	Five-day biochemical oxygen demand
BOD ₅ USABRDL	
	U.S. Army Biomedical Research and Development Laboratory
COD	Chemical oxygen demand
D0	Dissolved oxygen
F/M	Food-to-microorganism ratio
gpd	Gallons per day
gpm -	Gallons per minute
HDC	Holston Defense Corporation
HMX	Octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine
HPLC	High performance liquid chromatography
HSAAP	Holston Army Ammunition Plant
k BOD	Specific rate of BOD utilization
mgď	Million gallons per day
MLSS	Mixed liquor suspended solids
MLVSS	Mixed liquor volatile suspended solids
NH3-N	Ammonia nitrogen
N02-N	Nitrite nitrogen
N03-N	Nitrate nitrogen
NPDES	National Pollutant Discharge Elimination System
RDX	Hexahydro-1,3,5-trinitro-1,3,5-triazine
So	Influent total BODs
Š	Effluent soluble BODs
Se SEX	1-Acetyloctahydro-3,5,7-trinitro-1,3,5,7-tetrazocine
SVI	Sludge volume index
TAX	1-Acetylhexahydro-3,5-dinitro-1,3,5-triazine
TSS	Total suspended solids
X _V	Biomass (usually = MLVSS)
θ ^v	Sludge age
U	and a da

DISTRIBUTION LIST

No. of Copies

- Commander
 U.S. Army Medical Research and Development Command
 ATTN: SGRD-RMI-S
 Fort Detrick
 Frederick, MD 21701-5012
- Defense Technical Information Center (DTIC)
 ATTN: DTIC-FDAC
 Cameron Station
 Alexandria, VA 22304-6145
- Commandant
 Academy of Health Sciences, U.S. Army
 ATTN: HSHA-CDB
 Fort Sam Houston, TX 78234-6000
- Commander
 U.S. Army Biomedical Research and Development Laboratory
 ATTN; SGRD-UBZ-IL
 Fort Detrick
 Frederick, MD 21701-5010
- Commander
 U.S. Army Toxic and Hazardous Materials Agency
 ATTN: AMXTH-TE-D
 Aberdeen Proving Ground, MD 21010-5401
- Commander
 Holston Army Ammunition Plant
 ATTN: SMCHD-EN
 Kingsport, TN 37660-9982
- Commander
 U.S. Army Armament Research, Development and
 Engineering Center
 ATTN: SMCAR-AES-P
 Dover, NJ 07801-5001
